We propose a simple method for measuring the populations and the relative phase in a coherent superposition of two atomic states. The method is based on coupling the two states to a third common (excited) state by means of two laser pulses, and measuring the total fluorescence from the third state for several choices of the excitation pulses.

I. INTRODUCTION

Atoms and molecules prepared in well-defined coherent superpositions of energy states exhibit many interesting properties, such as dark resonances [1], subrecoil laser cooling [2–5], electromagnetically induced transparency [6–8], radiation amplification without population inversion [9–12], refractive index enhancement without absorption [13], and enhanced harmonic generation [14,15]. Coherent superpositions are essential to the implementation of quantum computation and quantum cryptography or, more generally, quantum information [16,17].

Various techniques are available for preparing coherent superpositions. Some of them are sensitive to pulse fluence (the time integrated pulse area), e.g., radio frequency or microwave excitation [18–20], resonant optical pulses [12], and trains of identical pulses [11]. Techniques based on stimulated Raman adiabatic passage (STIRAP) [21–23] are relatively insensitive to pulse area, e.g., fractional STIRAP [24–28] and tripod-linkage adiabatic passage [29].

To verify the reliability of these techniques it is essential to have a method for measuring the parameters of the created coherent superposition – the populations, the relative phase between the two states, and the degree of coherence. In this paper, we propose such a method. It is based on coupling the two states comprising the superposition to a third state (excited and subject to radiative decay), by means of two laser pulses, thus mapping the superposition parameters onto the population of the excited state. This population could then be observed either by fluorescence, by photoionization, or by recording with a channeltron the presence of an excited atom impinging upon a sensitive surface. By measuring the total signal from the excited state (for simplicity we shall refer to it as fluorescence) for four different combinations of laser polarizations one can deduce unambiguously the superposition parameters.

The method applies to superpositions of states that are unconnected by direct dipole coupling, but are linked by a two-photon transition. An example occurs with the frequently used superposition between the $m = -1$ and

$m = +1$ magnetic sublevels of a degenerate level having angular momentum $J = 1$. In the cases of fractional STIRAP [24–28] and in the tripod scheme [29], the excited state can be the one used in creating the superposition; no additional lasers are then required to implement the proposed superposition measurement.

This paper is organized as follows. In Sec. II we consider the ideal case when the initial superposition is a *pure* state, i.e., there is no incoherent population in the superposition. This allows us to present some of the fundamental principles in a simple way. In Sec. III we consider the general case when the initial superposition is a *mixed* state. This case is physically more realistic because there is usually a nonzero probability that during the preparation of the coherent superposition some of the atoms are pumped incoherently (e.g., by spontaneous emission) into one of the two states involved in the superposition. Finally, in Sec. IV we summarize the conclusions.

II. MEASURING A COMPLETELY COHERENT SUPERPOSITION (PURE STATE)

A. Theoretical background

1. Superposition parameters: Bloch and Poincaré spheres

We assume that the atom is prepared initially in a coherent superposition of two states ψ_1 and ψ_2 ,

$$\Psi = \psi_1 \cos \alpha + \psi_2 e^{i\varphi} \sin \alpha, \quad (1)$$

and we wish to determine the unknown superposition parameters – the mixing angle α ($0 \leq \alpha \leq \pi/2$) and the relative phase φ between ψ_1 and ψ_2 ($-\pi < \varphi \leq \pi$).

The parametrization of the superposition (1) by two angles is closely related to the parametrization of the Bloch vector, whose components are bilinear combinations of probability amplitudes. The dynamics of two-state excitation is often visualized by the motion of this vector on the Bloch sphere. Because the Bloch vector

FIG. 1. Sketch of the proposed scheme for measuring the coherent superposition of states ψ_1 and ψ_2 . The superposition parameters (the populations and the relative phase) are mapped onto the population of the excited state ψ_e by coupling state ψ_1 to ψ_e with the laser pulse Ω_1 and state ψ_2 to ψ_e with the laser pulse Ω_2 . The excitation pulses together obey a two-photon Raman-like resonance condition, although the individual pulses need not be resonant with their respective Bohr frequencies. The single-photon detuning is Δ .

length is set to unity for coherent excitation, the state of a coherent system is completely fixed by two angles. The azimuthal and polar angles of the Bloch vector for state (1) are given by $\pi - 2\alpha$ and $-\varphi$, respectively.

This parametrization of a two-state superposition is similar to the parametrization of polarized light by means of two angles that locate a point on the Poincaré sphere [30–32]. In the latter case there exist an infinite number of choices for the two independent orthogonal polarizations needed to characterize polarized light; orthogonal pairs lie at opposite poles on the sphere. In the case of coherent superpositions of nondegenerate states there is a natural basis – that of the two distinct energy states. When the atomic states are degenerate, as happens with magnetic sublevels, then the quantization axis – and the consequent definition of basis states – is arbitrary. The analogy between pairs of orthogonal polarization states and orthogonal atomic states is then complete.

2. Mapping the superposition parameters onto the population of an excited state

In order to determine the superposition parameters α and φ , we propose to use a pair of laser pulses, each of which couples one of the two superposed states ψ_1 and ψ_2 to a third (excited) state ψ_e , as shown in Fig. 1. The excitation produced by these pulses *maps* the initial superposition parameters onto the population of state ψ_e , thereby reducing the measurement of a coherent superposition to the easier measurement of population. Moreover, we shall show below that, by measuring the total fluorescence signal from the excited state for four different discrete combinations of laser parameters, one can determine unambiguously the parameters of the initial

superposition (1), without the necessity of knowing the exact probability of transition to the excited state.

In the mathematical description of this scheme, we assume applicability of the usual rotating-wave approximation (RWA), and take the time-varying interaction between states ψ_1 and ψ_e to be the Rabi frequency $\Omega_1(t)$, while the coupling between states ψ_2 and ψ_e is described by the Rabi frequency $\Omega_2(t)$. We require the two Rabi frequencies to have the same (pulsed) time dependence, as described by the envelope function $f(t/T)$ (with T being the pulse width), but we allow the fields to have different phases β_1 and β_2 and different peak Rabi frequencies A_1 and A_2 ,

$$\Omega_1(t) = A_1 f(t/T), \quad \Omega_2(t) = A_2 f(t/T). \quad (2)$$

We assume that the carrier frequencies for the two pulses together obey a two-photon Raman-like resonance condition, but we allow the possibility of nonzero single-photon detuning Δ . The RWA probability amplitudes of the three states obey the Schrödinger equation [32],

$$i\hbar \frac{d\mathbf{c}(t)}{dt} = \mathbf{H}(t)\mathbf{c}(t), \quad (3)$$

where $\mathbf{c}(t) = [c_1(t), c_e(t), c_2(t)]^T$ and $\mathbf{H}(t)$ is the RWA Hamiltonian,

$$\mathbf{H}(t) = \frac{\hbar}{2} \begin{bmatrix} 0 & \Omega_1(t)e^{-i\beta_1} & 0 \\ \Omega_1(t)e^{i\beta_1} & 2\Delta & \Omega_2(t)e^{-i\beta_2} \\ 0 & \Omega_2(t)e^{i\beta_2} & 0 \end{bmatrix}. \quad (4)$$

We wish to find the population $P_e = |c_e(+\infty)|^2$ of the excited state ψ_e after the excitation, provided the system has been initially in the superposition state (1).

Due to the two-photon resonance and the identical time dependence of $\Omega_1(t)$ and $\Omega_2(t)$, the three-state dynamics is reduced to that of a two-state system [33]. This is achieved by replacing states ψ_1 and ψ_2 with two alternative states, a “bright” state ψ_b and a “dark” state ψ_d , which are linear combinations of ψ_1 and ψ_2 ,

$$\psi_b = \psi_1 e^{-i\beta_1} \sin \vartheta + \psi_2 e^{i\beta_2} \cos \vartheta, \quad (5a)$$

$$\psi_d = \psi_1 e^{-i\beta_2} \cos \vartheta - \psi_2 e^{i\beta_1} \sin \vartheta, \quad (5b)$$

where the constant angle ϑ is defined by

$$\tan \vartheta = \frac{A_1}{A_2}, \quad (0 \leq \vartheta \leq \pi/2). \quad (6)$$

We stress that the bright and dark states are defined by the laser parameters and not by the initial atomic state.

In the bright-excited-dark basis, the dark state is decoupled from the other two states and its amplitude is conserved, $c_d(t) = \text{const}$. The three-state dynamics is thus reduced to a two-state one involving the bright and excited states whose amplitudes obey the equation

$$i \frac{d}{dt} \begin{bmatrix} c_b(t) \\ c_e(t) \end{bmatrix} = \frac{1}{2} \begin{bmatrix} 0 & \Omega(t) \\ \Omega(t) & 2\Delta \end{bmatrix} \begin{bmatrix} c_b(t) \\ c_e(t) \end{bmatrix}. \quad (7)$$

It is important that the two-state Hamiltonian in Eq. (7) depends only on the rms Rabi frequency,

$$\Omega(t) = \sqrt{\Omega_1(t)^2 + \Omega_2(t)^2}, \quad (8)$$

but not on the laser polarization ϑ and phases β_1 and β_2 .

The (unitary) transition matrix U^{be} for the effective two-state problem (7), which is defined by

$$\begin{bmatrix} c_b(+\infty) \\ c_e(+\infty) \end{bmatrix} = U^{be} \begin{bmatrix} c_b(-\infty) \\ c_e(-\infty) \end{bmatrix}, \quad (9)$$

can be parametrised by two complex numbers a and b as

$$U^{be} = \begin{bmatrix} a & b \\ -b^* & a^* \end{bmatrix}. \quad (10)$$

Then the transition matrix for the three-state problem in the bright-excited-dark basis is

$$U^{bed} = \begin{bmatrix} a & b & 0 \\ -b^* & a^* & 0 \\ 0 & 0 & 1 \end{bmatrix}. \quad (11)$$

By using the transformation back to the bare-state basis, we find that the transition matrix for the original three-state problem (3) is given in terms of a and b as

$$U = \begin{bmatrix} a \sin^2 \vartheta + \cos^2 \vartheta & b e^{-i\beta_1} \sin \vartheta & \frac{1}{2}(a-1)e^{-i\beta} \sin 2\vartheta \\ -b^* e^{i\beta_1} \sin \vartheta & a^* & -b^* e^{-i\beta_2} \cos \vartheta \\ \frac{1}{2}(a-1)e^{i\beta} \sin 2\vartheta & b e^{i\beta_2} \cos \vartheta & a \cos^2 \vartheta + \sin^2 \vartheta \end{bmatrix}, \quad (12)$$

with $\beta = \beta_1 + \beta_2$. By applying U on the initial vector (1), we find that the final population of state ψ_e is

$$P_e = p \left| \sin \vartheta \cos \alpha + e^{i(\varphi-\beta)} \cos \vartheta \sin \alpha \right|^2, \quad (13)$$

where $p = |b|^2$ is the transition probability in the equivalent two-state problem. For resonant excitation ($\Delta = 0$) we have $p = \sin^2 \int_{-\infty}^{+\infty} \Omega(t) dt$, whereas when $\Delta \neq 0$ the probability p depends on the detuning, on the pulse areas, and on the pulse shape $f(t/T)$. An important feature of our method is that we do *not* need the precise probability p because the dependence of P_e on p is factorized (this does not apply to P_1 and P_2 !). Hence, p can be eliminated simply by measuring P_e for different laser parameters and taking ratios.

B. Detecting a coherent superposition

The φ -dependence of the excited-state population (13) suggests a straightforward way of proving that a certain superposition is coherent. After the preparation of the superposition and prior to the application of the measuring laser fields, one can alter the superposition phase φ (e.g., by using pulsed magnetic field or off-resonance interaction) and plot the total fluorescence signal as a function of the parameter that alters the phase, e.g., the magnetic field B . A non-constant dependence of P_e on B is the indication of coherence.

C. Measuring a coherent superposition

Measuring the values of the superposition parameters α and φ is more complicated than just proving coherence. The result (13) suggests two possible methods of measuring α and φ .

1. Polarization measurement

Equation (13) shows that P_e vanishes when $\vartheta = \alpha$ and $\beta = \varphi + \pi$. In this case the superposition (1) coincides with the dark state. Hence, we can measure the superposition parameters α and φ by adjusting the ratio of the laser field amplitudes and the phase β until the fluorescence from state ψ_e disappears.

In the case when states ψ_1 and ψ_2 are the $m = -1$ and $m = +1$ magnetic sublevels of a $J = 1$ level and state ψ_e is the $m = 0$ sublevel of a $J = 0$ or $J = 1$ level [28,29], this can be done by using a single elliptically polarized laser pulse, which can be seen as a superposition of two circularly polarized σ^+ and σ^- pulses. The electric field of the elliptically polarized pulse in the complex representation $E(t) = E_x(t) + iE_y(t)$ is given by [30-32,34]

$$E(t) = E_1(t)e^{-i\omega t + i\beta_1} + E_2(t)e^{i\omega t + i\beta_2}. \quad (14)$$

The first term represents the σ^+ component and the second term is the σ^- component; hence, $E_1(t)/E_2(t) = A_1/A_2 = \tan \vartheta$. Here $\frac{1}{2}\beta = \frac{1}{2}(\beta_1 + \beta_2)$ is the angle of rotation of the polarization ellipse and $|E_1 - E_2|/(E_1 + E_2)$ is its axial ratio [30-32,34]. Measuring the superposition parameters in this manner, however, represents a two-dimensional optimization procedure which may be inconvenient, inefficient or inaccurate. We propose below an alternative method.

2. Population measurement

The alternative method consists of measuring several total fluorescence signals $\mathcal{I}_0(\vartheta, \beta)$ (the subscript zero stands for the fact that the initial superposition does not contain any incoherence) from state ψ_e for various sets of pulse pairs with different laser polarizations ϑ and phases β . Because fluorescence is proportional to the excited-state population, $\mathcal{I}_0(\vartheta, \beta) = \mathcal{N}P_e(\vartheta, \beta)$ ($\mathcal{N}$ being essentially the number of atoms), Eq. (13) suggests that it is convenient to make the following set of measurements:

$$\mathcal{I}_0(0, 0) = \mathcal{N}p \sin^2 \alpha, \quad (15a)$$

$$\mathcal{I}_0(\pi/2, 0) = \mathcal{N}p \cos^2 \alpha, \quad (15b)$$

$$\mathcal{I}_0(\pi/4, 0) = \frac{1}{2}\mathcal{N}p[1 + \sin 2\alpha \cos \varphi], \quad (15c)$$

$$\mathcal{I}_0(\pi/4, \pi/2) = \frac{1}{2}\mathcal{N}p[1 + \sin 2\alpha \sin \varphi]. \quad (15d)$$

In the case when states ψ_1 and ψ_2 are the $m = -1$ and $m = +1$ sublevels of a $J = 1$ level and one uses a single

elliptically polarized laser pulse with the field (14), the first two cases (15a) and (15b) correspond to σ^+ or σ^- polarizations, respectively. The third and fourth cases correspond to linear polarizations, the latter being rotated to 45 degree with respect to the former.

The parameters of the initial superposition (1) can easily be derived from the fluorescence signals as follows:

$$\tan^2 \alpha = \frac{\mathcal{I}_0(0, 0)}{\mathcal{I}_0(\pi/2, 0)}, \quad (16a)$$

$$\cos \varphi = \frac{2\mathcal{I}_0(\pi/4, 0) - \mathcal{I}_0(0, 0) - \mathcal{I}_0(\pi/2, 0)}{2\sqrt{\mathcal{I}_0(0, 0)\mathcal{I}_0(\pi/2, 0)}}, \quad (16b)$$

$$\sin \varphi = \frac{2\mathcal{I}_0(\pi/4, \pi/2) - \mathcal{I}_0(0, 0) - \mathcal{I}_0(\pi/2, 0)}{2\sqrt{\mathcal{I}_0(0, 0)\mathcal{I}_0(\pi/2, 0)}}. \quad (16c)$$

Knowing $\tan^2 \alpha$ is sufficient for the determination of α because $0 \leq \alpha \leq \pi/2$. In order to find φ , however, we need to know both $\cos \varphi$ and $\sin \varphi$ because φ is defined in the interval $(-\pi, \pi]$. Hence, we need *four* separate measurements of the total fluorescence from the excited state ψ_e . This method appears easier to implement than the two-dimensional optimization discussed above.

The set of four measurements taken with different settings of two angles is reminiscent of the settings of phase retardation angles in the measurement of Stokes parameters [30]; the connection will be further discussed in Sec. III.

Finally, as Eq. (13) shows, P_e depends on the detuning and on the laser intensity through p only. Hence, the superposition parameters α and φ obtained by either methods described above should not depend on laser power, detuning and pulse shape.

III. MEASURING A PARTIALLY COHERENT SUPERPOSITION (MIXED STATE)

A. Density matrix description: analogy with partially polarized light

The most general presentation of the properties of a two-state system is by means of its density matrix. The diagonal elements are real (and non-negative) and sum to unity, and the off-diagonal elements are complex conjugates of each other, so that a total of three real numbers suffice to completely specify a two-state system. The additional parameter, beyond the two parameters needed to describe a coherent superposition, expresses the degree of incoherence between the two states.

The density matrix description of a two-state atom has an analog in the use of a coherence matrix to describe partially polarized light as a mixture of elliptically polarized light and unpolarized light. A common parametrization of such light is by means of the four Stokes parameters s_j ($j = 0, 1, 2, 3$), which can be regarded as the coefficients in the expansion of the density matrix in terms of the Pauli matrices and the unit matrix. One of the

Stokes parameters (s_0) measures the trace of the coherence matrix (or overall intensity), and is not of interest in the present context.

As is discussed in standard textbooks, the determination of the four Stokes parameters can be accomplished with a set of six intensity measurements, each involving a projection onto a pure polarization: a pair of σ^+ and σ^- circular polarizations, a pair of x and y linear polarizations, and a pair of linear polarizations rotated at 45 degree. Three of the Stokes parameters can be regarded as associated with projection of the polarization onto the three choices of (complex) unit vectors: having introduced such a projection onto a particular pair of orthogonal polarizations, the Stokes parameter is the difference between the two orthogonal components.

A similar procedure can be applied to the case of two degenerate atomic states linked, by electric dipole transitions, to an excited state. The basic idea is to project the two-dimensional space of atomic states onto various orthogonal axes, defined by the polarization of the electric field that occurs in the interaction $-\mathbf{d} \cdot \mathbf{E}$. The measurement pulses map these projections onto the population of the excited state ψ_e .

It should be emphasized that two of the six polarization measurements are redundant. Indeed, in the method we describe below only four independent measurements of the fluorescence from the excited state are required.

B. Mapping the superposition parameters onto the excited-state population

The time evolution of the density matrix $\rho \equiv \rho(t)$ of the three-state system obeys the Liouville equation

$$i\hbar\dot{\rho} = [\mathbf{H}, \rho], \quad (17)$$

where $\mathbf{H}(t)$ is the RWA Hamiltonian (4) and

$$\rho = \begin{bmatrix} \rho_{11} & \rho_{1e} & \rho_{12} \\ \rho_{e1} & \rho_{ee} & \rho_{e2} \\ \rho_{21} & \rho_{2e} & \rho_{22} \end{bmatrix}. \quad (18)$$

Explicitly, the density-matrix equations read

$$i\dot{\rho}_{11} = \Omega_1 (e^{-i\beta_1} \rho_{e1} - e^{i\beta_1} \rho_{1e}), \quad (19a)$$

$$i\dot{\rho}_{22} = \Omega_2 (e^{i\beta_2} \rho_{e2} - e^{-i\beta_2} \rho_{2e}), \quad (19b)$$

$$i\dot{\rho}_{ee} = \Omega_1 (e^{i\beta_1} \rho_{1e} - e^{-i\beta_1} \rho_{e1}) + \Omega_2 (e^{-i\beta_2} \rho_{2e} - e^{i\beta_2} \rho_{e2}), \quad (19c)$$

$$i\dot{\rho}_{12} = \Omega_1 e^{-i\beta_1} \rho_{e2} - \Omega_2 e^{-i\beta_2} \rho_{1e}, \quad (19d)$$

$$i\dot{\rho}_{1e} = \Omega_1 e^{-i\beta_1} (\rho_{ee} - \rho_{11}) - \Omega_2 e^{i\beta_2} \rho_{12} - \Delta \rho_{1e}, \quad (19e)$$

$$i\dot{\rho}_{2e} = \Omega_2 e^{-i\beta_2} (\rho_{ee} - \rho_{22}) - \Omega_1 e^{-i\beta_1} \rho_{21} - \Delta \rho_{2e}. \quad (19f)$$

As in the fully coherent case (Sec. II), the equations of motion simplify considerably in the bright-excited-dark basis; there the density-matrix elements read

$$\begin{aligned}\rho_{bb} &= \rho_{11} \sin^2 \vartheta + \rho_{22} \cos^2 \vartheta \\ &+ (e^{i\beta} \rho_{12} + e^{-i\beta} \rho_{21}) \sin \vartheta \cos \vartheta,\end{aligned}\quad (20a)$$

$$\begin{aligned}\rho_{dd} &= \rho_{11} \cos^2 \vartheta + \rho_{22} \sin^2 \vartheta \\ &- (e^{i\beta} \rho_{12} + e^{-i\beta} \rho_{21}) \sin \vartheta \cos \vartheta,\end{aligned}\quad (20b)$$

$$\begin{aligned}\rho_{bd} &= (\rho_{11} - \rho_{22}) \sin \vartheta \cos \vartheta e^{i(\beta_1 - \beta_2)} \\ &- \rho_{12} e^{2i\beta_1} \sin^2 \vartheta + \rho_{21} e^{-2i\beta_2} \cos^2 \vartheta,\end{aligned}\quad (20c)$$

$$\rho_{be} = \rho_{1e} e^{i\beta_1} \sin \vartheta + \rho_{2e} e^{-i\beta_2} \cos \vartheta, \quad (20d)$$

$$\rho_{de} = \rho_{1e} e^{i\beta_2} \cos \vartheta - \rho_{2e} e^{-i\beta_1} \sin \vartheta, \quad (20e)$$

The six coupled density-matrix equations (19) decompose into three uncoupled sets of equations: one equation expressing the conservation of the dark-state population,

$$i\dot{\rho}_{dd} = 0; \quad (21)$$

two coupled equations for the dark-state coherences,

$$i\dot{\rho}_{db} = \Omega \rho_{de}, \quad (22a)$$

$$i\dot{\rho}_{de} = -\Omega \rho_{db} - \Delta \rho_{de}; \quad (22b)$$

and, as befits the two-state dynamics, three coupled equations involving the bright and excited states,

$$i\dot{\rho}_{bb} = \Omega (\rho_{eb} - \rho_{be}), \quad (23a)$$

$$i\dot{\rho}_{ee} = \Omega (\rho_{be} - \rho_{eb}), \quad (23b)$$

$$i\dot{\rho}_{be} = \Omega (\rho_{ee} - \rho_{bb}) - \Delta \rho_{be}. \quad (23c)$$

Because the fluorescence signal is proportional to the excited-state population ρ_{ee} , we are only interested in the third set of equations (23). It is important that Eqs. (23) depend only on Ω and Δ , but not on the laser polarization ϑ and phases β_1 and β_2 . The *initial conditions*, though, depend on ϑ and $\beta = \beta_1 + \beta_2$; they are

$$\begin{aligned}\rho_{bb}(-\infty) &= \rho_{11}(-\infty) \sin^2 \vartheta + \rho_{22}(-\infty) \cos^2 \vartheta \\ &+ [e^{i\beta} \rho_{12}(-\infty) + e^{-i\beta} \rho_{21}(-\infty)] \sin \vartheta \cos \vartheta,\end{aligned}\quad (24a)$$

$$\rho_{ee}(-\infty) = \rho_{be}(-\infty) = 0. \quad (24b)$$

(as the system is initially in a superposition of states ψ_1 and ψ_2 only, all density-matrix elements involving ψ_e vanish initially). It follows from Eqs. (24) and from the fact that Eqs. (23) are linear differential equations that the excited-state population ρ_{ee} is expressible as

$$\rho_{ee}(+\infty) = \mathcal{P} \rho_{bb}(-\infty), \quad (25)$$

where the probability $\mathcal{P}$ depends only on $\Omega(t)$ and Δ , but not on ϑ and β . Hence, when we vary the polarization and the phases of the two laser fields, while keeping $\Omega(t)$ and Δ unchanged, the change in the fluorescence signal will derive entirely from the change in the initial bright-state population $\rho_{bb}(-\infty)$. This factorization (25) of $\rho_{ee}(+\infty)$ is very important because it allows us to avoid the necessity of knowing the probability $\mathcal{P}$ and thus eliminates the dependence on $\Omega(t)$ and Δ .

C. Determination of the density matrix

Equations (24a) and (25) suggest a simple procedure for the determination of the initial density-matrix elements by measuring the total fluorescence $\mathcal{I}(\vartheta, \beta)$ from the excited state. We need only *four measurements* for different polarization parameters ϑ and β . As in Sec. II, a suitable choice is the following set of measurements:

$$\mathcal{I}(0, 0) = \mathcal{N} \mathcal{P} \rho_{22}(-\infty), \quad (26a)$$

$$\mathcal{I}(\pi/2, 0) = \mathcal{N} \mathcal{P} \rho_{11}(-\infty), \quad (26b)$$

$$\begin{aligned}\mathcal{I}(\pi/4, 0) &= \frac{1}{2} \mathcal{N} \mathcal{P} [\rho_{11}(-\infty) + \rho_{22}(-\infty) \\ &+ 2\text{Re} \rho_{12}(-\infty)],\end{aligned}\quad (26c)$$

$$\begin{aligned}\mathcal{I}(\pi/4, \pi/2) &= \frac{1}{2} \mathcal{N} \mathcal{P} [\rho_{11}(-\infty) + \rho_{22}(-\infty) \\ &- 2\text{Im} \rho_{12}(-\infty)],\end{aligned}\quad (26d)$$

where we have used the relation $\mathcal{I}(\vartheta, \beta) = \mathcal{N} P_e(\vartheta, \beta)$. Because $\rho_{11}(-\infty) + \rho_{22}(-\infty) = 1$, we have $\mathcal{N} \mathcal{P} = \mathcal{I}(0, 0) + \mathcal{I}(\pi/2, 0)$. Hence the initial density-matrix elements are given by

$$\rho_{11}(-\infty) = \frac{\mathcal{I}(0, 0)}{\mathcal{I}(0, 0) + \mathcal{I}(\pi/2, 0)}, \quad (27a)$$

$$\rho_{22}(-\infty) = \frac{\mathcal{I}(\pi/2, 0)}{\mathcal{I}(0, 0) + \mathcal{I}(\pi/2, 0)}, \quad (27b)$$

$$\text{Re} \rho_{12}(-\infty) = \frac{\mathcal{I}(\pi/4, 0)}{\mathcal{I}(0, 0) + \mathcal{I}(\pi/2, 0)} - \frac{1}{2}, \quad (27c)$$

$$\text{Im} \rho_{12}(-\infty) = \frac{1}{2} - \frac{\mathcal{I}(\pi/4, \pi/2)}{\mathcal{I}(0, 0) + \mathcal{I}(\pi/2, 0)}. \quad (27d)$$

D. Determination of the superposition parameters

Once we know the density matrix, it is easy to find its incoherent part ρ^{inc} and its coherent part ρ^{coh} by using the decomposition (we drop the argument $-\infty$ hereafter)

$$\rho = \rho^{\text{inc}} + \rho^{\text{coh}} = \begin{bmatrix} r^{\text{inc}} & 0 \\ 0 & r^{\text{inc}} \end{bmatrix} + \begin{bmatrix} \rho_{11}^{\text{coh}} & \rho_{12}^{\text{coh}} \\ \rho_{21}^{\text{coh}} & \rho_{22}^{\text{coh}} \end{bmatrix}, \quad (28)$$

and the coherence relation $\rho_{11}^{\text{coh}} \rho_{22}^{\text{coh}} - \rho_{12}^{\text{coh}} \rho_{21}^{\text{coh}} = 0$. The explicit expressions are readily found [30],

$$\rho_{11}^{\text{coh}} = \frac{1}{2} \left[\rho_{11} - \rho_{22} + \sqrt{(\rho_{11} - \rho_{22})^2 + 4|\rho_{12}|^2} \right], \quad (29a)$$

$$\rho_{22}^{\text{coh}} = \frac{1}{2} \left[\rho_{22} - \rho_{11} + \sqrt{(\rho_{11} - \rho_{22})^2 + 4|\rho_{12}|^2} \right], \quad (29b)$$

$$\rho_{12}^{\text{coh}} = \rho_{12}, \quad (29c)$$

$$r^{\text{inc}} = \frac{1}{2} \left[\rho_{11} + \rho_{22} - \sqrt{(\rho_{11} - \rho_{22})^2 + 4|\rho_{12}|^2} \right]. \quad (30)$$

From here we can determine the *degree of coherence* of the initial superposition, which is defined as the ratio

$\text{Tr}\rho^{\text{coh}}/\text{Tr}\rho$ between the trace of the coherent part of the density matrix ρ^{coh} and the trace of the total density matrix $\rho = \rho^{\text{inc}} + \rho^{\text{coh}}$ ($\text{Tr}\rho \equiv 1$),

$$\text{Tr}\rho^{\text{coh}} = \sqrt{(\rho_{11} - \rho_{22})^2 + 4|\rho_{12}|^2}. \quad (31)$$

The degree of coherence is equal to the length of the Bloch vector [32]. The parameters characterizing the coherent part of the superposition – the mixing angle α and the relative phase φ – can be found from the relations

$$\tan^2 \alpha = \frac{\rho_{22}^{\text{coh}}}{\rho_{11}^{\text{coh}}}, \quad (32a)$$

$$\varphi = -\arg \rho_{12}^{\text{coh}}. \quad (32b)$$

It is easy to verify that in the case of a pure state ($r^{\text{inc}} = 0$), Eqs. (32) reduce to Eqs. (16).

IV. CONCLUSION

In this paper, we have proposed a method for measuring the parameters of a coherent superposition of two atomic states. It is based upon coupling the two states to a third excited state by means of two laser pulses, thus mapping the superposition parameters onto the population of this state. By measuring the total fluorescence signal from this state for *four* different polarizations of the two pulses we can determine unambiguously the parameters of the initial superposition – the populations, the relative phase between the participating states, and the degree of coherence. The method requires a proper control of the polarizations and the relative phase between the two laser fields. In addition, the two laser pulses have to be short compared to the lifetime of the excited state in order to avoid spontaneous emission back to the superposition that would introduce additional incoherence. On the other hand, the method has the advantage that no knowledge is required of the exact probability of transition to the excited state; this makes it invariant against laser power, detuning, and pulse shape, as long as these are kept constant during the four measurements. Finally, the method is particularly suited for the frequently used superpositions between the $m = -1$ and $m = 1$ magnetic sublevels of a $J = 1$ level because then only one laser is needed; this laser can be the same as the one used in the preparation of the superposition.
